T zone lymphoma (TZL) is characterized by the clonal expansion of T cells lacking expression of the pan-leukocyte antigen CD45 (TZ cells). A strong breed predisposition is observed in Golden retrievers. This study aimed to confirm aberrant CD45 mRNA expression and determine if Golden retrievers without clinical lymphoma have an increased frequency of circulating TZ cells. Gene expression analysis on confirmed TZL cases showed a significant decrease in CD45 expression compared to normal dogs. Peripheral blood samples from senior dogs, 242 Golden retrievers and 42 non-Golden retrievers, without evidence of lymphoproliferative disease were assessed for the presence of TZ cells by flow cytometry. Thirty-one percent of Golden retrievers had TZ cells compared to 14% of non-Golden retrievers. Thirty-four percent of Golden retrievers with TZ cells had a clonal T cell receptor gamma (TRG) gene rearrangement. Interestingly, 20% of Golden retrievers without TZ cells also had a clonal TRG rearrangement. Golden retrievers may have an increased risk of TZL due to an increased frequency of TZ cells.

1 | INTRODUCTION

Canine lymphoproliferative disease characterization has improved with the use of ancillary diagnostics including immunocytochemistry, immunohistochemistry, flow cytometry, PCR for antigen receptor rearrangement (PARR) and, more recently, gene expression profiling. Many of the canine lymphoproliferative diseases mimic human disorders and efforts have been made to utilize the World Health Organization scheme when classifying canine lymphoma. As these subtypes become more completely defined, some marked breed-specific predispositions for different subtypes have become evident. For example, Boxers and Golden retrievers (GRs) are highly represented amongst the group of dogs that develop an aggressive form of T cell lymphoma, histologically characterized as lymphoblastic lymphoma or peripheral T cell lymphoma not otherwise specified (PTCL-NOS). Another example includes a recent study in which small breed dogs were found to be over-represented in the group of dogs that develops B cell chronic lymphocytic leukemia. Breed-specific tendencies to develop particular disorders indicate a high likelihood for genetic risk factors underlying these diseases, and position the dog as a useful model for studying the role of genes in the development of lymphoproliferative disease.

T zone (or clear cell) lymphoma (TZL) is a variant of PTCL-NOS that is described in both humans and dogs. TZL is characterized by neoplastic T cells expanding the paracortex and medullary cords and compressing the fading germinal centres. The cells are small to intermediate in size with very rare mitoses. The prevalence of TZL is estimated as 3% to 14% of all canine lymphomas in two different large-scale studies and there is a striking breed predilection in dogs, with 40% of all TZL cases being diagnosed in American GRs. European GRs, which represent a discreet genetic group do not appear to be over-represented in TZL. The median age of dogs diagnosed with TZL is 10 years in multiple studies. Lymphadenopathy and lymphocytosis are both commonly associated with TZL, and the presence of TZL in the blood does not appear to indicate a more aggressive clinical course. The overall median survival time is reported to be 760 to 1022 days, consistent with an indolent nature. The disease is often detected as an incidental finding of lymphocytosis and/or lymphadenopathy; interestingly 10% to 50% of cases present with or develop demodecic mange, suggesting that the TZL may cause immunosuppression in a subset of cases. TZL exhibits a unique phenotype: the neoplastic T cells do not express the pan-leukocyte antigen CD45, allowing for reliable
diagnosis by immunophenotyping. Recently this was corroborated with immunohistochemistry. Additionally, real-time PCR for CD45 transcript and DNA showed almost complete lack of CD45 gene expression but presence of CD45 DNA. CD45 is a transmembrane protein tyrosine phosphatase that has multiple isoforms that are abundantly expressed on the cell surface of all leukocytes. Two major isoforms of CD45 have been recognized in canine T cells, with expression varying based on phenotype and activation status. The T cell receptor (TCR) is closely associated with CD45, and CD45 expression is necessary for T cell response to antigen.

T zone (TZ) cells express increased levels of the complement receptor CD21, which is commonly used to identify B cells in dogs. In previous studies, CD21 expression has been identified by flow cytometry and with microarray in TZL. However, expression was not compared with normal T cells in these studies. The neoplastic cells can express CD4, CD8, neither subset antigen, or, rarely, both.

Our laboratory is conducting a study of environmental and genetic risk factors for TZL in GRs. While screening control GRs (dogs ≥9 years with no clinical evidence of lymphoma of any type), we discovered that many dogs had small but detectable numbers of CD5+ CD45− cells (TZ cells) in their peripheral blood. This observation caused us to ask if TZ cells are equally frequent in all dogs over the age of 9 or if this is a breed-specific phenomenon.

The objectives of this study are 2-fold. First, we wanted to validate in detail the phenotype of TZ cells by examining mRNA levels for the proteins that characterize these cells: CD45 and CD21. Then, we wanted to determine the frequency of TZ cells in non-lymphoma bearing older GRs and other purebred dogs. We hypothesized that TZ cells would be found more frequently in GRs than other breeds reflecting the breed predilection observed for this form of lymphoma. Validation of this hypothesis would suggest that an early event in the development of TZL is loss of CD45 expression, and would pave the way for mechanistic studies of oncogenesis.

2 MATERIAL AND METHODS

2.1 Selection of cases and controls for gene expression analysis

To investigate the aberrant antigen expression seen in TZL, we measured the levels of CD45 and CD21 mRNA from case and control samples. Case samples included blood or lymph node aspirates from 34 dogs diagnosed with TZL by flow cytometry through the Colorado State University Clinical Immunology (CSU-CI) laboratory between December 2013 and March 2015. These cases were not breed restricted. A diagnosis of TZL included greater than 60% of the lymphocytes characterized as TZ cells (CD5+ CD45− cells) in lymph node samples or the presence of ≥5000 TZ cells/μL in the peripheral blood of dogs with lymphadenopathy or lymphocytosis, respectively. These criteria were based on previous publications in which the minimum criteria for the diagnosis of lymphoid malignancy was 60% or greater aberrant cells in a lymph node, or 5000 cells/μL or greater phenotypically homogeneous expansion of lymphocytes in peripheral blood. The control group consisted of T cells purified from lymph node and thymic tissue collected from 8 young, healthy, hound mix dogs that were being utilized for a surgical continuing education course. All these procedures were approved by the IACUC committee at Colorado State University.

2.2 Cell sorting for gene expression studies

2.2.1 TZL cases

TZ cells were purified from blood or lymph node of TZL cases by negatively selecting CD45-expressing cells. Briefly, based on the Miltenyi Biotec protocol, the nucleated cells were re-suspended in MACS buffer (Phosphate-buffered saline [PBS]-0.5% BSA-2 mM Ethylenediaminetetraacetic acid [EDTA] −1 mM resulting in a total volume of 100 μL after addition of the primary antibodies. All antibodies were purchased from Abd Serotec/Bio-Rad (Kidlington, UK). Anti-CD45 PE (Pan-leukocyte, clone YKIX716.13) at a concentration of 0.01 μg/μL was added and the samples were incubated for 10 minutes in the dark at 4°C and then washed with MACS buffer. The supernatant was removed and samples were re-suspended in 80–90 μL of MACS buffer and 10 μL of anti-PE beads (Miltenyi Biotec, San Diego, California). The samples were incubated for 10 minutes in the dark at 4°C and washed with MACS buffer. The supernatant was removed and the cells were re-suspended in 500 μL of MACS buffer. For magnetic depletion of CD45+ cells, the 500-μL cell suspension was loaded onto an LD column that had been placed into a MidiMACS separator. CD45− cells that were not bound by beads were collected and tested for purity by flow cytometry. Figure 1 shows an example of sorted CD5+ CD45− (TZ) cells purified by this method. The median purity of the sorted TZ cells was 98%, and only one sample had lower than 90% purity (82%).

2.2.2 Controls

CD4 and CD8 T cells were purified from the lymph nodes and thymus of 8 healthy control dogs to be used as normal controls in a series of studies of gene expression profiling in T cell lymphoma. Cells were stained with anti-CD18-PE (Human CD18, clone YFC118.3), anti-CD5-FITC (T cells, clone YKIX322.3) and either anti-CD4-Pacific Blue (CD4 T cells, clone YKIZ302.9) or anti-CD8-FITC (CD8 T cells, clone YCATE 55.9) and sorted by fluorescence-activated cell sorting on a MoFlo cell sorter (Beckman Coulter, Brea, California). All samples were analyzed for purity and only those samples with 90% of the desired cells were used for RNA purification.

2.3 Gene expression using NanoString technology

Expression of CD45 and CD21 was measured using NanoString technology. NanoString technology was employed because it does not require high quantity or quality of RNA, such as RNA derived from convenience clinical samples that have been shipped and then further manipulated once arriving in the laboratory. Only 100 ng or less of total RNA is needed, the detection method has a 0.1 to 0.5 fm detection limit and the assay is reproducible (R²=.999 average for replicates). Gene expression is measured by counting the number of transcripts for each gene of interest, rather than using relative expression as is done with microarrays, and there is no PCR amplification step.
After sorting, the cell fractions were suspended in RNA lysis buffer prepared according to the Purelink RNA mini kit (Life Technologies, Carlsbad, California) and stored at $-80^\circ$ C until analysis. RNA samples were analyzed for degradation and concentration using Agilent RNA ScreenTape assay (Agilent Technologies, Santa Clara, California). Samples had concentrations ranging from 1250 to 129,000 pg/μL and RNA integrity numbers (RINs) ranging from 2.6 to 7.6. Approximately, 100 ng of purified RNA per sample was hybridized overnight to the mRNA custom-built probes and hybridized reactions were loaded into the nCounter Digital Analyzer (NanoString Technologies, Seattle, Washington) through the University of Arizona Genetic Core.

Probes were designed based on the predicted sequence of Canis lupus familiaris CD45. While multiple CD45 isoforms have been annotated in the dog, only two isoforms have been shown to be expressed in the dog. The difference in these two isoforms is the presence or absence of exon 4, which is included in the larger molecular weight form of CD45.18 Exon 4 is expressed by naïve T cells, but not expressed in the majority of activated and memory T cells in humans.15,24 Therefore, two probes were designed to detect CD45 expression (Figure 2, Table 1). The probe designed for PTPRCb was a pan-CD45 probe predicted to bind to both demonstrated canine isoforms18 as well as all predicted possible canine isoforms by analogy with mouse and human studies.17 The second probe, PTPRCa, was predicted only to bind to the higher molecular weight isoform of CD45 (Figure 2).

The CD21 probe was designed to detect all three predicted canine isoforms of this protein (Table 1). Gene expression was normalized using 6 housekeeping genes (Table 1) which were chosen from a group of 15 housekeeping genes because they exhibited low variability between dogs.

2.4 | Selection of dogs for quantifying CD45– T cells in peripheral blood

The frequency of TZ cells in the peripheral blood was assessed in 2 populations of dogs: GRs and non-Golden retrievers (non-GRs).

![FIGURE 1] Example of T zone (TZ) cells purified from one dog for gene expression. A and B are plots from the peripheral blood before sorting for TZ cells, and C and D are plots from the same sample of peripheral blood after purification of TZ cells. The TZ cells are in the TZ gate, normal T cells are in the CD5 gate. A and C depict light scatter properties. B and D depict expression of CD5 and CD45. After the sort, the sample is composed of 99.93% TZ cells.

![FIGURE 2] CD45 splice variants. Graphical depiction of CD45 mRNA, predicted splice variants and mapping of designed probes for PTPRCa and PTPRCb. Each red arrow represents an exon and the first 4 exons are enumerated.
GR samples were obtained from the control group of a case–control study of risk factors for TRL being conducted by the CSU-CI laboratory. Samples from dogs collected from June 2013 to April 2015 were utilized. Criteria for controls for this study included GRs, 9 years of age or older, with no suspicion or history of lymphoproliferative disease and no lymphocytosis. Other medical conditions, including cancers other than lymphoma/leukaemia, did not exclude dogs from the study. Clinical signs were reported by veterinarians based on physical examinations and history obtained during sample submission. Non-GR dogs were selected from dogs presenting to the Colorado State University Veterinary Teaching Hospital (CSU-VTH) between April 2014 and January 2015. Shih tzu, which were reported to be the second most frequent breed to develop TRL, were excluded from this study and will be part of a separate investigation. Medical records were reviewed to identify purebred dogs, 9 years and older. Dogs with prior diagnosis or evidence of lymphomata (T and B cells). If 1% or fewer of the lymphocytes were T cells the dog was considered to be negative for TZ cells and was categorized as such in both the GR and non-GR populations.

2.6 | Clonality testing

The presence of a clonally expanded lymphocyte population was detected by PARR for the TRG as previously described with modifications noted in Table S1 and Figure S1 (Appendix S1). The amount of blood used for each reaction was 200 μL and a result was considered clonal if 1 or 2 peaks were seen in the electropherogram that were greater than ×3 the baseline. Equivocal clonal TRG gene rearrangements were identified when the peak height did not quite reach the ×3 threshold, but was nonetheless prominent.

2.7 | Statistical analysis

nCounter software (NanoString Technologies) was used to carry out the normalization of mRNA levels in the gene expression study. To compare gene expression between cases and controls, a Student’s t test was performed (Prism 6; Graphpad, La Jolla, California). The gene expression value was reported as the absolute number of transcripts, which was transformed to the signal log2(ratio) a (signal log2 ratio of 1 is equal to a fold change of 2) to determine the P value. To compare the prevalence of TZ cells in the peripheral blood of GRs vs non-GRs and the percentage of GRs (with and without TZ cells) with a TRG clonal result, a Pearson’s Chi-squared test was performed. Differences in breed, sex and haematological characteristics were analyzed using Pearson’s Chi-squared tests (Prism 6). Median age between groups was compared using the Mann-Whitney test. Statistical significance was defined as P < .05.

a Unless otherwise noted, all antibodies were purchased from AbD Serotec/Bio-Rad. Clones are as follows: CD45 = YKIX16.13, CD18 = YFC118.3 (human CD18), CD4 = YKIX302.9, CD8 = YCATE 55.9, CD5 = YKIX322.3, CD21 = CA2.1D6, CD22 = RB6 (human CD22, purchased from AbCam, Cambridge, UK), CD3 = CA17.2A12, CD14 = TUK4 (human), class II MHC = YKIX334.2, CD34 = 1H6, CD25 = P2A10 (purchased from eBioscience, San Diego, CA).
3  |  RESULTS

3.1  |  Gene expression of CD45 and CD21

We first wanted to validate the observation that TZ cells downregulate CD45 and upregulate CD21 by measuring mRNA levels, since expression of these two proteins has been described as unique features of TZL.9,14,19,20 Forty-eight samples (14 sorted T cell controls and 34 TZL cases) from lymph node, peripheral blood and thymus (controls only), were analyzed for mRNA counts using NanoString technology.

The results showed that the mean log₂-transformed CD45 mRNA counts in TZ cells was 5.2- to 8.4-fold (log₂-fold change) lower than in controls (P < .0001, Table 3) depending on the isoform detected. CD21 mRNA counts were more variable among TZL cases, but the median value was 3.3-fold higher than CD21 mRNA counts in controls (Table 3) (P < .0001). These findings indicate that mRNA levels reflect protein expression, and verify that the antibodies used for these studies are recognizing the appropriate corresponding proteins. Furthermore, the results support previous findings that no variant of CD45 is expressed by the TZ cells.

3.2  |  Frequency of TZ cells in senior GRs and non-GRs purebred dogs

We enumerated TZ cells in 242 peripheral blood samples from GRs. Seventy-four of these dogs (30.6%) had variable numbers of TZ cells in their peripheral blood. This was significantly higher than the percentage of non-GRs with TZ cells in the peripheral blood (P = .03).

The percentage of TZ cells varied from 2% to 95% of all T cells, median = 18.1% (Figure 3). The median fluorescence intensity (MFI) of CD21 in TZ cells (Median MFI = 7.3) compared to normal T cells in the same dog (Median MFI = 0.37) was significantly higher (median difference = 7.0, P < .0001) (Figure 4). In GRs, the size of TZ cells (median size = 361) was also significantly larger than normal T cells (median size = 342) with a median difference of 15.21 (P = .0003).

Abbreviation: IQR, interquartile range.

a Normalized mRNA counts.

FIGURE 3  A and B show T zone (TZ) cells in a healthy Golden retriever (GR). In this sample, the number of TZ cells represented 95% of the total T cell population, the highest percentage of TZ cells detected in non-lymphoma bearing GRs. C and D show TZ cells in a non-Golden retriever (non-GR), the highest percentage TZ cells detected in the blood of non-GRs. In this sample, the number of TZ cells represented 20% of the total T cell population. E shows the range of TZ cells in GRs (n = 74, median = 18.1%) vs non-GRs (n = 6, median = 17.4%). The whiskers are set at the minimum and maximum value.
Of the 42 non-GRs, there were 6 (14%) dogs with small numbers of TZ cells identified by flow cytometry and 36 dogs without TZ cells. Among the 6 dogs with TZ cells, the proportion of TZ cells ranged from 6% to 20% of all T cells, median = 17.4% (Figure 3). In dogs with TZ cells, the MFI of CD21 in TZ cells (Median MFI = 0.55) compared with normal T cells (Median MFI = 12) was significantly higher (median difference = 11.5, \( P < .03 \)) (Figure 4). There was no significant difference in the size of TZ cells vs normal T cells in non-GR dogs. There was no significant difference in age, sex, presence of anaemia or presence of thrombocytopenia between the dogs with TZ cells and the dogs without TZ cells in either the GR group or the non-GR group.

### 3.3 | Clonality assessment

PARR was performed in 67 of the 74 cases of GRs with TZ cells (Table 4). Twenty-three (34.3%) of the cases had clonal TRG gene rearrangements, 1 dog (1.5%) had an equivocal result and 43 (64.2%) were polyclonal. Additionally, 32 (20%) of 157 GRs with no evidence of TZ cells in peripheral blood had a clonal TRG gene rearrangement. The percentage of GRs with TZ cells with a clonal TRG gene rearrangement was significantly higher than the percentage of GRs without TZ cells with a clonal TRG result (\( P = .026 \)).

All 6 non-GRs with TZ cells had PARR performed, and all had polyclonal TRG gene rearrangements, demonstrating no evidence for clonality (Table 4). The PARR assay was performed on 34 of the non-GRs without TZ cells and 2 had a clonal TRG gene rearrangement. The clonal TRG gene rearrangements in these dogs may have represented an emerging T cell lymphoma/leukaemia although this cannot be confirmed because both dogs were euthanized shortly after the sample was obtained due to progressive transitional cell tumour of the bladder in one dog and progressive immune-mediated haemolytic anaemia in the other.

### 3.4 | Follow-up studies of GRs with TZ cells

Sequential peripheral blood samples were available for 50 dogs within the entire population of GRs. Twenty-two of these dogs had TZ cells in the first sample and all these dogs also had TZ cells in the follow-up sample. Twenty-eight dogs had no TZ cells in the first sample. Of these, 12 had TZ cells in the follow-up sample and the remaining 16 did not. At the time of this manuscript preparation, none of these dogs have developed evidence of clinical disease, in particular lymphocytosis or peripheral lymphadenopathy.

PARR was performed on 45 of these samples and the results did not change for 42 of the dogs. In 3 dogs, however, the PARR assay changed from a polyclonal to clonal result in the follow-up sample. These 3 dogs had TZ cells in their blood on both occasions.

### 4 | DISCUSSION

In this study, we have found that the loss of CD45 antigen expression and the increased expression of CD21 by TZ cells is reflected in the expression of the relevant genes. These findings indicate that the abnormal antigen expression in TZL is not a function of conformational changes in the antigen, or in the case of CD45, differentially spliced protein that is not detected by the antibody used in the analysis and support recent findings from another group.\(^1\)\(^4\) The expression of CD21 in TZL in our study is in concordance with previously identified CD21 expression by flow cytometry,\(^9\)\(^1\)\(^9\) and increased CD21 (CR2) gene expression identified in dogs with TZL using the Affymetrix Canine_2.0 gene chip.\(^2\)\(^0\) In our study, the isolation methods for TZL cases differed from the isolation of normal T cells because of the limitations imposed by the use of samples submitted for diagnostic purposes. However, the purity and quality of RNA was similar for

\( n \) indicates the number of samples available for the PARR assay. The percentage is the number of samples with that result out of the total samples with a PARR result.
both cell types and our results are supportive of other investigations into phenotypic abnormalities of TZL. These findings further characterize these aberrancies as occurring at both the protein and mRNA level, and support the characterization of this particular subtype of lymphoma in dogs by immunophenotyping. We have demonstrated that 31% of GRs with no evidence of lymphoma/leukaemia have circulating TZ cells. These cells can be identified in 14% of older dogs of other breeds. These proportions reflect the distribution of the biological significance of TZ cells and possible identification of other genetic and environmental factors involved in the development of TZL is ongoing.

In conclusion, TZ cells were identified in greater than 30% of GRs, the breed with the highest number of dogs to develop TZL. These cells are readily identified by flow cytometry and aberrant antigen expression is confirmed at the gene expression level. We have found that a higher percentage of GRs without lymphoma have TZ cells in their blood when compared with other purebreds, and this reflects the frequency with which GRs develop TZL. Additionally, the lack of clinical signs or progression to disease in these dogs suggests that this is still a pre-neoplastic state despite evidence of clonal TRG gene rearrangement. Given these findings, clonal TRG gene rearrangements should be interpreted with caution in non-clinical older dogs, particularly GRs. Continued prospective analysis of GRs to determine the biological significance of TZ cells and possible identification of other genetic and environmental factors involved in the development of TZL is ongoing.
